ABSTRACT

Understanding the direct electron transfer processes between redox proteins and electrode surface is fundamental to understand the proteins mechanistic properties and for development of novel biosensors. In this study, nitric oxide reductase (NOR) extracted from *Marinobacter hydrocarbonoclasticus* bacteria was adsorbed onto a pyrolytic graphite electrode (PGE) to develop an unmediated enzymatic biosensor (PGE/NOR) for characterization of NOR direct electrochemical behaviour and NOR electroanalytical features towards NO and O₂. Square-wave voltammetry showed the reduction potential of all the four NOR redox centers: 0.095 ± 0.002 , -0.108 ± 0.008 , -0.328 ± 0.001 and -0.635 ± 0.004 V vs. SCE for heme c, heme b, heme b₃ and non-heme Fe_B, respectively. The determined sensitivity ($-4.00 \times 10^{-8} \pm 1.84 \times 10^{-9}$ A/ μ M and $-2.71 \times 10^{-8} \pm 1.44 \times 10^{-9}$ A/ μ M for NO and O₂, respectively), limit of detection (0.5 μ M for NO and 1.0 μ M for O₂) and the Michaelis Menten constant (2.1 and 7.0 μ M for NO and O₂, respectively) corroborated the higher affinity of NOR for its natural substrate (NO). No significant interference on sensitivity towards NO was perceived in the presence of O₂, while the O₂ reduction was markedly and negatively impacted (3.6 times lower sensitivity) by the presence of NO. These results clearly demonstrate the high potential of NOR for the design of innovative NO biosensors.

1. Introduction

Biological denitrification is an anaerobic pathway used by different bacteria to generate energy [1]. In denitrification, the reduction of nitrate to dinitrogen gas is accomplished by four different types of metalloenzymes (nitrate reductase, nitrite reductase, nitric oxide reductase (NOR) and nitrous oxide reductase) in four simple steps (nitrate → nitrite → nitric oxide → nitrous oxide → dinitrogen gas) [1]. In the third step, two nitric oxide radicals (*NO, herein abbreviated NO) are conjugated to form nitrous oxide and water in a two electron/proton reaction ($2\text{NO} + 2\text{e}^- + 2\text{H}^+ \rightarrow \text{N}_2\text{O} + \text{H}_2\text{O}$ (Eq. (1))) with the involvement of NOR. NO is a signalling molecule involved in important biological processes in humans including neurotransmission, vasodilation, platelet aggregation, gene expression and apoptosis [2]. NO has also been implicated in a wide range of pathological processes, such as chronic infections and inflammations, diabetes, and neurological diseases (Parkinson and Alzheimer) [3]. Concerning NOR, three classes (cNOR, CuNOR and qNOR) exist, which are composed by different electron

transfer centers and subunits [4]. cNOR, the first class, is a membrane enzyme with two different subunits, a NorB (the catalytic center) and a NorC (responsible for electron transfer) [5,6]. cNOR can be extracted from *Paracoccus denitrificans* [7–9], *Pseudomonas nautica* (also designated as *Marinobacter hydrocarbonoclasticus*) [5,10,11], *Pseudomonas aeruginosa* [12,13], *Halomonas halodenitrificans* [14], *Roseobacter denitrificans* [15] and *Thermus thermophilus* [16].

Several methods have been applied to study the NO reduction by different NORs, which included density functional theory (DFT) calculations [7,12,17], fluorescence [18], Raman [19,20] and UV/Vis spectroscopy [21,22]. More recently, electrochemical methods, mainly cyclic voltammetry [5,10,11] and spectroelectrochemistry [8] have been also explored due to their inherent advantages, namely inexpensive instrumentation, possibility of miniaturization, requirement of low volumes, high sensitivity and low limits of detection (LOD) [23–26]. Electrochemical biosensors, in particular third-generation biosensors (based on direct electron transfer (DET), i.e. in the absence of mediators, [27–31]) are the next promising step to detect NO in vivo studies.

Recent works have permitted to obtain crucial information on NOR catalysis behaviour towards NO, however, some questions still remain

* Corresponding author.

E-mail address: sbm@isep.ipp.pt (S. Morais).

unanswered due to controversial opinions [5,10]. One of those questions rely on the competition between the two most important substrates of this enzyme, NO and O₂. Therefore, in this study, NOR purified from *Marinobacter hydrocarbonoclasticus* was adsorbed onto a pyrolytic graphite electrode (PGE) to produce an unmediated enzymatic biosensor (PGE/NOR) for characterization of NOR electroanalytical features towards NO and O₂. In addition, the direct electrochemical behaviour of the purified NOR was evaluated.

2. Materials and methods

2.1. Reagents

n-dodecyl-β-D-maltoside (DM), di-potassium hydrogen phosphate (K₂HPO₄, >99%) and sulfuric acid (H₂SO₄, 96%) were purchased from Panreac (Spain), 2-phenylethanol (PE, ≥99.0%) from Sigma-Aldrich (Germany) and ethanol (>96%) from Carlo Erba (Italy). Potassium hydroxide (KOH, 87.50%) and potassium dihydrogen phosphate (KH₂PO₄, 99.50%) were bought from Pronolab (Mexico) and Merck (USA), respectively. NO and O₂ with the desired concentrations were prepared by dilution from buffer stock solutions. NO solutions of different concentrations were prepared by dilution from a buffer stock solution of 100 μM prepared by bubbling a 5% NO/95% He gas mixture (Air Liquid, Portugal) into phosphate buffer 100 mM pH 6.0. For the O₂ effect study, the O₂ concentration was varied by adding different volumes of air-equilibrated water (assumed as being 245 μM at 25 °C) to the anaerobic reaction mixture. All solutions and stock were prepared immediately before being used. Ultrapure water obtained from a Millipore water purification system (18 MΩ, Milli-Q; Millipore, Molsheim, France) was used in all experiments.

2.2. NOR purification and characterization

NOR is not commercially available and it was purified from membrane extracts of *Marinobacter hydrocarbonoclasticus* grown anaerobically as described by Prudêncio et al. [32]. The enzyme purity was estimated by its UV-visible spectrum (Abs₄₁₀/Abs₂₈₀ ratio of 1.3; UV 1800-Shimadzu, Germany) [33] and electrophoresis assays under denaturation conditions (tricine SDS-PAGE) (Bio-Rad, Mini-PROTEAN® Tetra Handcast Systems, Portugal) based on the protocol of Laemmli [34]. Two bands corresponding to NOR subunits (NorC (17 kDa) and NorB (35–40 kDa)) were obtained and are in agreement with those presented by Girsch and de Vries [35]. Moreover, the specific activity of the purified NOR of 760 U/mg was determined by amperometry with an ISO-NO sensor (2 mm, World Precision Instruments, Inc., UK: one unit corresponds to 1 μmol of NO/min) as described previously by Timóteo et al. [33].

2.3. Biosensor preparation

PGE was sequentially hand polished with 5.0, 1.0 and 0.3 μm alumina (Gravimeta Lda, Portugal), briefly sonicated with ethanol and finally rinsed with ultrapure water. Surface activation was performed by cyclic voltammetry (CV) in 0.5 M H₂SO₄ at 100 Vs⁻¹ in the range of 0 to 1.6 V vs. saturated calomel electrode (SCE). NOR (7 μL of 14 mg/mL – 760 U/mg) was then immobilized on the PGE surface (0.4 cm diameter) using the solvent casting technique and dried using ultra-pure argon [36]. All the assays were conducted inside an anaerobic chamber (MBraun UniLab, Germany), at room temperature, where O₂ concentration was set at 0.1 ppm.

2.4. Electrochemical measurements

The PGE/NOR was set as the working electrode, and a platinum wire and SCE were the secondary and reference electrodes, respectively. The three-electrode system was connected to an μAUTOLAB potentiostat

controlled by GPES 4.9.7 software (Eco Chimie). The redox behaviour of NOR was evaluated by CV at different scan rates (from 0.10 to 2.0 Vs⁻¹) in a potential range of 0.4 to –0.9 V with a previous deoxygenation of the buffer solution (100 mM potassium phosphate buffer, 0.02% (v/v) DM and 0.01% PE at pH 6.0) using ultra-pure argon gas during 20 min. For the O₂ effect study, the O₂ concentration was varied by adding different volumes of air-equilibrated water (assumed as being 245 μM at 25 °C) to the anaerobic reaction mixture. Bioelectrocatalytic studies of NO and O₂ reduction were performed by CV at 5 mV/s and by square wave voltammetry (SWV) at 8 Hz, step potential of 6 mV and amplitude of 20 mV in the same, as previously described, potential range.

3. Results and discussion

3.1. Characterization of the nitric oxide reductase-based biosensor

The characterization of the DET of the purified NOR was firstly performed by CV at 0.50 Vs⁻¹ in buffer solution (100 mM potassium phosphate, 0.02% DM and 0.01% PE) at pH 6.0 under anaerobic conditions (Fig. 1(A)). The pH of 6.0 was chosen based on the previous data reported by Duarte et al. [5] and Garny et al. [37] since, at this value, maximum enzyme catalytic activity was attained due to the protonation of the residues surrounding the catalytic centre. A cathodic (at 0.28 V) and an anodic (at 0.26 V) peak were detected with a formal potential (E⁰) of –0.27 ± 0.01 V at 0.50 Vs⁻¹ corresponding to the low spin heme b₃ of the NOR bi-nuclear catalytic center, which is related to the reduction/oxidation of heme-(Fe(III)/Fe(II)) groups in accordance with Cordas et al. [10]. The observed cathodic (I_{pc}) and anodic (I_{pa}) peak current ratio (I_{pa}/I_{pc}) ≈ 1 and the linear regressions of the I_{pc} and I_{pa} versus the tested scan rates (ν; 0.10 to 2.0 Vs⁻¹) (Fig. 1(B)); I_{pc} (A) = –2.56 × 10⁻⁶ ± 4.70 × 10⁻⁸ ν (Vs⁻¹) – 1.32 × 10⁻⁷ ± 3.68 × 10⁻⁸; r² = 0.997; n = 10 and I_{pa}(A) = 2.60 × 10⁻⁶ ± 4.90 × 10⁻⁸ ν (Vs⁻¹) + 7.17 × 10⁻⁸ ± 3.83 × 10⁻⁸; r² = 0.997; n = 10) indicated that this is a surface electron-transfer process with no diffusion control [38]. The peak to peak separation (ΔE_p) was ≈ 0 mV for the highest scan rates (0.35 to 2.00 V/s), which is in agreement with the theoretical value for ideal surfaces, but ΔE_p ≈ 30 mV for the lowest scan rates (0.1 to 0.23 V/s). This profile could be influenced by the amino acids around the heme b₃, the protonation states of ligands to the heme iron or the protonation of the water molecule coordinated to the iron center [39]. SWV assays allowed to observe the other NOR redox centers in addition to the redox signal of the previously described heme b₃-center (Fig. 1(C)), due to the SWV higher sensitivity when compared with CV. The NOR reduction potential was determined for heme c, heme b, heme b₃ and non-heme Fe_B as being 0.095 ± 0.002, –0.108 ± 0.008, –0.328 ± 0.001 and –0.635 ± 0.004 V, respectively (Fig. 1(C)) (at 50 Hz, step potential of 5 mV and amplitude of 20 mV). These results are in agreement with those previously reported for formal potentials of NOR (Table 1) with non-significant deviations, except for heme c with a value of –0.033 ± 0.017 V (this peak is less defined than the others, which may promote higher potentials discrepancies). Dependence between the peak current and the scan rate was perceived for all three redox centers that were not detected by CV (heme c: I_p (A) = –9.83 × 10⁻⁷ ± 1.62 × 10⁻⁷ ν (Vs⁻¹) – 2.75 × 10⁻⁸ ± 3.64 × 10⁻⁸; r² = 0.995; n = 6; heme b: I_p (A) = –1.04 × 10⁻⁶ ± 6.28 × 10⁻⁸ ν (Vs⁻¹) + 4.09 × 10⁻⁸ ± 2.33 × 10⁻⁸; r² = 0.99; n = 7; non-heme Fe_B: I_p (A) = –2.05 × 10⁻⁶ ± 1.67 × 10⁻⁷ ν (Vs⁻¹) – 2.75 × 10⁻⁷ ± 4.66 × 10⁻⁸; r² = 0.994; n = 7) (Fig. 1(D)).

The surface concentration of the electroactive species and rate constant were also determined using the obtained electrochemical data. The surface concentration of the electroactive species (Γ*, molcm⁻²) was estimated based on Eq. 2 [40]:

$$Q = nF\Gamma\tau^* \quad (2)$$

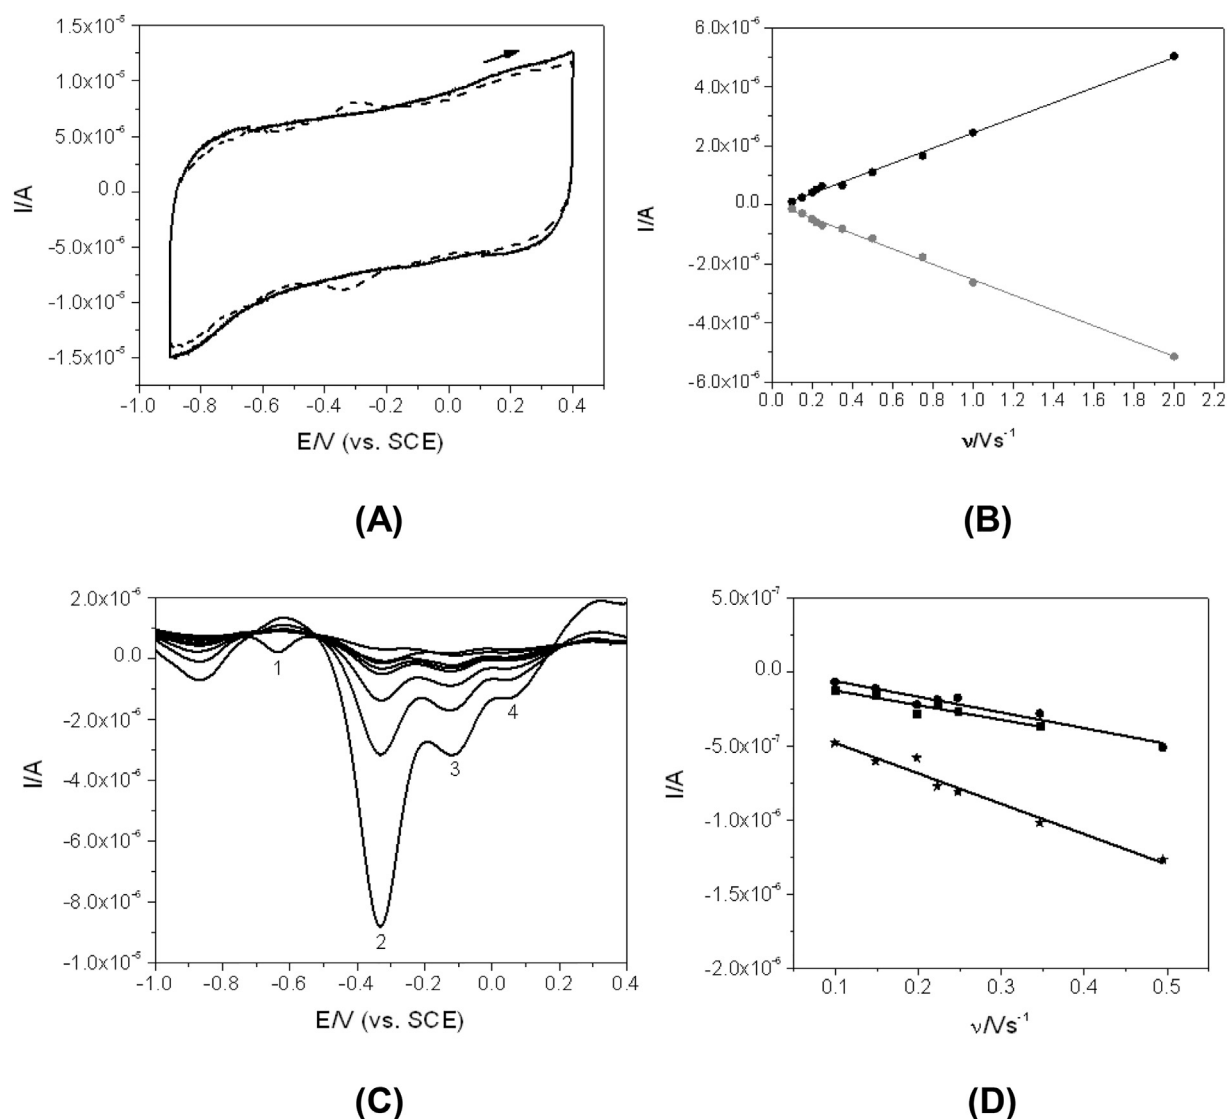

Fig. 1. (A) Representative cyclic voltammograms of the electrochemical behavior of PGE (—) and PGE/NOR (---) in buffer solution at 0.50 Vs^{-1} . (B) Influence of the scan rate ($0.10, 0.15, 0.20, 0.22, 0.25, 0.35, 0.50, 0.75, 1.0$ and 2.0 Vs^{-1}) on the oxidation (●) and reduction (●) peak current of the principal heme center of NOR (heme b_3). (C) Square-wave voltammograms of PGE/NOR biosensor at different frequencies (20, 30, 40, 45, 50, 70, 100 and 150 Hz) (step potential of 5 mV and amplitude of 20 mV) showing the non-heme Fe_B (1), heme b_3 (2), heme b (3) and heme c (4) peak centers. (D) Influence of the scan rate ($0.10, 0.15, 0.20, 0.22, 0.25, 0.35$ and 0.50 Vs^{-1}) on the reduction peak current of non-heme Fe_B (*), heme b (●) and heme c (■) peak centers. Experimental conditions: Assays were performed under anaerobic conditions in 100 mM potassium phosphate pH 6.0, 0.02% *n*-dodecyl- β -D-maltoside and 0.01% 2-phenylethanol.

where Q (A.s) is the charge involved in the reaction, A (cm^2) is the geometric area of the working electrode, n is the number of the electron transferred, F ($\text{sA} \cdot \text{mol}^{-1}$) is the Faraday constant, as being $1.2 \times 10^{-11} \text{ molcm}^{-2}$, corresponding to a multilayer coating. By applying

the Laviron model [41], a value of the rate constant, k_s , for the redox reaction of the catalytic heme b_3 centre was assessed as 0.60 s^{-1} , demonstrating the good electron transfer between NOR and the electrode surface.

3.2. Nitric oxide bioelectrocatalysis

In this work, the NO bioelectrocatalysis by the PGE/NOR was followed by SWV and CV (Fig. 2). Heme proteins-modified electrodes using haemoglobin, myoglobin, cytochrome c, among others, have been applied for the detection of NO [42–44]. NOR, a specific bacterial heme protein, bioelectrocatalyses directly the NO to N₂O reduction (-0.71 ± 0.01 V; Fig. 2 (A)) with the release of water according to the reaction $2\text{NO} + 2e^- + 2\text{H}^+ \rightarrow \text{N}_2\text{O} + \text{H}_2\text{O}$ (Eq. (3)) [7], thus avoiding the necessity of using electroactive mediators. NOR catalytic subunit (NorB) is formed by a low-spin heme b and a singular catalytic diiron center constituted by the heme b₃ and one non-heme iron (Fe_B), which are bridged by a μ -oxo/hydroxo group [45]. This special feature, when compared to the other proteins, seems to have a crucial role on the NOR higher specificity and efficiency for NO reduction, making it a very interesting target to develop new NO biosensors. Moreover, free energy profiles for NO reduction by NOR have been originating important information on its mechanism proving that it needs low activation energy to efficiently catalyze the NO reduction [7,12,15]. The irreversible behavior of NO reduction at the developed biosensor may be observed in Fig. 2 (B); Fig. 2 ((C)–(D)) exhibit the attained calibration curve data (square wave voltammograms and corresponding mean regression equation) when the PGE/NOR was exposed to different concentration of dissolved NO (0.50 to 6.98 μM): I_p (A) = $-4.00 \times 10^{-8} \pm 1.84 \times 10^{-9}$ [NO] (μM) - $1.36 \times 10^{-7} \pm 6.78 \times 10^{-9}$; $r^2 = 0.99$; $n = 6$. These results were used to determine the detection (LOD; $3 \times$ the standard deviation of the y-intercept (Sy)/slope) and quantification (LOQ; $10 \times$ Sy-intercept/slope) limits [46], as being 0.5 and 1.7 μM , respectively. The Michaelis-Menten constant (K_m) was also estimated according to the Michaelis-Menten equation (Eq. 4).

$$I_{ss} = I_{max}[C]/(K_m + [C]) \quad (4)$$

where I_{ss} (A) is the current after addition of the substrate; C (μM) is the concentration of the substrate; I_{max} (A) is the maximum current measured under saturated substrate conditions [47]. The attained K_m value, 2.1 μM , is similar to 2.2 μM , which was reported by Duarte et al. [5] proving the great affinity of the purified NOR for the NO substrate (Table 1). This behaviour may be due to the efficient orientated immobilization of the catalytic center of NOR and its availability for NO reduction [5]. The determined catalytic rate constant (k_{cat}), 1.82 s^{-1} , is lower than the previously attained using steady-state kinetic experiments with NOR immobilized onto a graphite rotating disk electrode, mimicking the role of the physiological partner [5]. However, these comparisons should be made with caution since significantly different experimental setups and concentration ranges were used.

NOR was shown to be a divergent member of the superfamily of O₂-reducing heme copper oxidases [48]. This enzyme was also reported to be catalytically active towards O₂ reduction through the following reaction: $\text{O}_2 + 4\text{H}^+ + 4e^- \rightarrow 2\text{H}_2\text{O}$ (Eq. (5)) [17]. Therefore, the influence of O₂ (at 5.98 μM) on the NO reduction was similarly characterized. No significant interference on sensitivity towards NO was perceived since the following data were achieved: I_p (A) = $-3.76 \times 10^{-8} \pm 1.95 \times 10^{-9}$ [NO] (μM) - $9.87 \times 10^{-8} \pm 7.19 \times 10^{-9}$; $r^2 = 0.99$; $n = 6$ (Fig. 2(E)–(F)); the ratio between regression equation slopes (in the absence and presence of O₂) was 1.06. These results also suggested that the reaction between NO and O₂ to yield nitrogen dioxide radical, according to Eq. 6 under the low (physiological) NO concentrations [49,50], did not significantly contribute to the consumption of NO.

Nevertheless, it should be noted that this reaction (Eq. 6) also interferes with the aerobic NO measurements by any (bio)sensor or methodology. Therefore, the attained biosensor sensitivity seems adequate to

determine the NO release in biological systems or in environmental studies under anaerobic or aerobic conditions.

3.3. Dioxygen bioelectrocatalysis

Using the same approach as the one applied for NO, the O₂ bioelectrocatalysis by NOR was studied by CV and SWV in the absence (Fig. 3(A)–(D)) and in the presence (Fig. 3(E)–(F)) of NO. The efficient O₂ bioelectrocatalysis by NOR promoted the appearance of an irreversible reduction peak at -0.25 ± 0.02 V (Fig. 3(A)–(C)), which increased linearly with the O₂ concentration from 1.22 to 11.67 μM . When NO was introduced at the 2.44 μM level, a significant negative impact on the biosensor sensitivity towards O₂ was perceived with a value about 3.6 times lower (I_p (A) = $-7.57 \times 10^{-9} \pm 2.71 \times 10^{-10}$ [O₂] (μM) - $8.06 \times 10^{-10} \pm 1.09 \times 10^{-9}$; $r^2 = 0.994$; $n = 6$) than the reached in the absence of NO (I_p (A) = $-2.71 \times 10^{-8} \pm 1.44 \times 10^{-9}$ [O₂] (μM) - $3.93 \times 10^{-8} \pm 9.89 \times 10^{-9}$; $r^2 = 0.99$; $n = 6$). On the other hand, the peak current of NO did not suffered any marked effect due to the augmentation of the O₂ concentration in the electrolyte, being stable at $1.89 \times 10^{-7} \pm 9.00 \times 10^{-9}$ A (RSD = 4.8% at 2.44 μM ; $n = 6$) (Fig. 3(E)–(F)). As expected, the determined LOD (1.0 μM) and LOQ (3.2 μM) values for O₂ electroanalysis were considerably higher than those reached for NO detection. Also, the greater Michaelis-Menten constant value (7.0 μM), when compared to the K_m obtained for the bioelectrocatalysis of NO (2.1 μM), reinforced the higher affinity of NOR to NO and the preference of this enzyme for its natural substrate.

4. Conclusions

A third generation biosensor composed by PGE/NOR was used to characterize the NOR electrochemical behaviour. Considering that NOR is catalytically active towards NO and O₂ reduction, the bioelectrocatalysis of these two substrates, under anaerobic conditions, was studied when both existed separately and when the two substrates were in competitive environment. NOR demonstrated to have affinity for both substrates but exhibited a lower Michaelis-Menten constant (2.1 for NO vs. 7.0 μM for O₂) for its natural substrate (NO). The attained high sensitivity for NO suggests the potential applicability of this NOR-based biosensor to real biological samples in aerobic conditions and demonstrate the possibility of using NOR in the design of unmediated nitric oxide biosensors. Still, further studies are needed to characterize other possible interfering substrates existing in real matrices. Moreover, future research is being undertaken to enhance the NOR electron transfer rate and lifetime at the PGE.
